"FA" function in CMOS

CMOS technology CMOS technology (Complementary Metal Oxide Semiconductor) offers two types of transistors called "N-channel" and "P-channel". CMOS is currently the dominant technology, at least for digital circuits. Its main advantage with respect to other technologies is remarkable low power consumption. Indeed the CMOS circuits exhibit a static current (or quiescent current) practically negligible. In the figures below :

- A logic '1' is represented by the supply voltage Vdd (current values for Vdd are +5V or +3,3V or +2,8V) and is colored in red.
- A logic '0' is connected to the ground voltage, or GND, is colored in **blue**.
- A connection neither to Vdd nor to GND is in yellow.

The N-channel transistor conducts when it gate is '1' and the P-channel transistor

conducts when its gate is '0' The keys 🖞 📩 change the transistor's outline.

CMOS inverter The CMOS inverter is the most popular gate. It is composed of a N-channel and a P-channel transistors connected through their drain. The figure below illustrates its behavior.

The colors conventions are still red for logic '1' and blue for logic'0' An input voltage in between causes a (mild) short-circuit by maintaining both transistors in conduction. Such a voltage is colored in **green**. Click on input "a" to pass from '0' to short (**green**), then to '1', then to short (**green**) again then back to '0' and so on.

Please notice that when the input is '0' or '1', only one transistor conducts.

Delay and We just have seen that the inverter dissipates no energy except during commutation.

dissipation of the Indeed if the input is '0' or '1' there is no conduction path between the power supply CMOS inverter Vdd and the ground GND. In normal conditions, the short circuit current, $x \to y$ (unavoidable during input commutation) lasts a very short time, typically a few picosecondes.

> The contribution of the parasitic capacitances charge or discharge is much more significant. The transistor gate G forms a capacitance. Anyway this capacitance is necessary to the field effect transistor working. Typically an input capacitance Cgmay be around 10 fF. If at time t_1 , this capacitance is connected to Vdd it is charged (charge Q = Cg * Vdd). If later on, at time t_2 , the input is connected to GND the capacitance is discharged. This discharge causes a current in the gate I = dQ/dt = $(Cg * Vdd)/(t_2 - t_1).$

Although the gate charge/discharge current is Let us take an example :

- A modern microprocessor may contain 50 million transistors, meaning about 10 million gates. For each clock cycle, about 1% of those gate commutates.
- Clock frequency may reach 1 000 MHz (cycle time 1 ns) with a power supply Vdd = 3.3V.
- The wires connecting the gates most of the time exhibit a parasitic capacitance Cw much larger than the gate input capacitance Cg. Each a wire commutates, all the attached capacitances must be either charged or discharged. : Ctotal = Cg + Cw.
- An average wire capacitance may be around 1 pF

It is rather difficult to estimate the current due to the short-circuits, it is generally small. On the contrary the current due to the commutation activity is important : $I = (active \ gates)*(Ctotal*Vdd) / dt = (1\% * 1,000,000) * (1pF * 3.3V) / 2ns = 16A$

Finally the quiescent current due to the transistors leaks is quite small (for a conventional circuitry). A static memory SRAM of 2K*8 bits in CMOS let leak $1 \,\mu A$ when not active.

- The figure below shows the current, or electrons ⊖ flow in the CMOS inverter. • Whenever the input stays to '1' or to '0', either the N-channel of the P-channel transistor is blocked and there is no current
- When the input changes, the grid of the two transistors must be charged or • discharged. This is illustrated by the flow of an electron Θ (with a negative charge) coming from GND or going to Vss.
- During the input change, the voltage passes through values that let both transistors conduct, usually during a very short time. This short-circuit current is illustrated by an electron flowing directly from GND to Vss.
- Finally the output is charged or discharged through the transistors. The output capacitance stores two electrons Θ .

The power dissipated by a conventional CMOS circuit is consequently directly proportional to the clock frequency.

<u>a</u>

Electrical By clicking or dragging the mouse inside the chronogram below, you control the simulation of the input "a" voltage (plotted in red on the chronogram). The output voltage "y" is then CMOS inverter computed (plotted in blue). The current flowing through the N-channel transistor if y_ drawn in green and the current through the P-channel transistor is in yellow. To suspend the applet and freeze the plot, just get the pointer out of the picture.

Applet for inverter electrical simulation.

Click here to start the simulation.

Move the pointer out of the picture to stall the simulation. Click in the picture to plot the input voltage "a" (in red).

output voltage "y".

N-channel transistor current.

P-channel transistor current.

Basic NOR and We are now studying some basic CMOS logic gate: a 2-input NOR, a 2-input NAND gates NAND and finally a full adder cell.

> Colors conventions: They are the same as the inverter's one. Connections to Vdd (logic '1') are drawn in red, connections to GND (logic '0') are in blue, and connections to both Vdd and GND are in green. Finally connections neither to Vdd nor to GND (floating) are in **vellow**. The two last colors have no logic image.

- Click close to an input changes its value and consequently the state of the transistors attached to this input.
- The line in the truth table that corresponds to the input combination is highlighted.
- Clicking in the truth table changes the input according to the highlighted line.

Clicking the top of the table highlight the next line. •

To simplify the applets, only logical '1' and '0' are allowed for the inputs. Therefore it is not possible to input a value causing a short-circuit between Vdd and GND

Two-input NOR The two-input "NOR" gate is one of the simplest gates to illustrate the term gate complementary : the P-channel transistors are connected in serial while the N-channel transistors are in parallel. The P-channel and N-channel network are y_ complementary.

> Notice that when none of the two P-channel transistors conduct, their common connection is floating (yellow). This is a "non logic" value, however, it does not cause trouble since it is not connected to any transistor gate.

The 2-input NAND In the two-input NAND gate, the P-channel transistors are connected in parallel gate while the two N-channel transistors are in serial.

<u>a</u>

b

У

Binary adder The "Full Adder" cell (FA) is made of two connected complex gates. It realizes an arithmetic equality: the weighted sum of the three inputs "x", "y" et "z" is always equal to the weighted sum of the two outputs "c" et "s", in other words "x + y + z =2*c + s ". This property can easily be checked thanks to the cell truth table.

The P-channel transistor network is symmetrical to the N-channel network. A circuit with this property is called "mirror". All the adders exhibit the property that follows from an arithmetic link between the logic and arithmetic complements. Finally the two circuit outputs are inverted. This follows from an electric property of the CMOS technology, which allows easily non-increasing logical functions only.

Adders

"FA" cell In the "FA" cell, the weighted sum of the output bits equals the weighted sum of the output bits, i.e. " x + y + z = 2*c + s ". The three input bits share the same

bit "c" weight is double (2). The "FA" cell conserves the sum just like the node conserves the electric current in the "Kirchoff's current law".

weight. Let it be "1". The output bit "s" has also the same weight, while the output

The "FA" cell is also called " $3 \Rightarrow 2$ compressor" since it reduces the bit number from 3 to 2 while preserving the *numerical value*.

Carry propagate adder The addition is by far the most common arithmetic operation in digital processors. Addition is itself very frequent and is also the basis of most other arithmetic operations like multiplication, division, square root extraction and elementary functions.

All "consistent" "FA" cells assembling preserves the property: *the weighed sum of the output bits equals the weighted sum of the input bits*.

To construct the adder S = A + B, the input bits come from the two numbers A and B and the output bits form the number S.

The number of "FA" cells is the same as the number of bits of A and B.

Performance of Let us assume that all the possible values for A and B are equiprobable and the carry ripple independent:

adder

	minimum	average	maximum
delay	0	log ₂ (n)	n
activity	0	3n / 4	$n^2/2$

The maximum delay (worst case) is usually not acceptable. Let us examine the carry propagation path that causes this delay.

Carry For each "FA" cell, one of the three following case occurs:

- **propagation** the carry c_{i+1} is set to '0', noted 'K', if $a_i = 0$ and $b_i = 0$
 - **path** the carry c_{i+1} is set to '1', noted 'G', if $a_i = 1$ and $b_i = 1$
 - the carry c_{i+1} is propagated, noted 'P', if $(a_i = 0 \text{ and } b_i = 1)$ or $(a_i = 1 \text{ and } b_i = 0)$. In this last case $c_{i+1} = c_i$. This is the unfavorable case, materialized by an horizontal arrow in the next applet.

The three case 'K', 'G' and 'P' are encoded onto two 2 bits.

''BK'' cell The "BK" cell computes the carry for two binary positions (two "FA" cells) or more (**Brent & Kung** generally two blocks of "FA" cells.

Sklansky's To design fast adders, binary trees of "BK" cells will first generate simultaneously all the carries c_i. The "Sklanski's adder" builds recursively 2-bit adders, 4-bit adders, 8-bit adders, 16-bit adder and so on by abutting each time two smaller adders. The architecture is simple and regular, but may suffer from fan-out problems. Besides in most of the cases it is possible to use less "BK" cells for the same delay.

Fast adders (Brent & Kung) In a fast adder, <u>all the carries</u> c_i are computed <u>simultaneously</u> through a binary tree of "BK" cells. To save on complexity, sharable intermediate results are computed once. There is only <u>one rule</u> to construct the trees: every output with position i must be connected to <u>all inputs</u> of position less than or equal to i by a tree of "BK" cells. The rule simplicity usually allows for many correct constructions.

In the "BK" cell tree, one may trade cells for delay, usually for the same addition the less the delay, the more the "BK" cells.

- change the number of bits and/or the delay
- check that the trees follow the construction rule by clicking on a signal (a line), notice that each signal is named by a pair of integers.
- simulate the carries computation by clicking on the keys K.
- display the tree construction process by clicking the key "Details"
- display the adder VHDL description by clicking the key "VHDL". To save the VHDL description, select it, then copy and paste it into a text editor.

Kogge & StoneThe binary trees of "BK" cells in the Kogge et Stone adders are not sharing.addersConsequently the signal fan out is reduced to the minimum at the expense of more
"BK" cells. Since the delay increases with the fan-out, it is here a bit shorter.

- **Ling adder** In the Ling's adder, the "BK" trees give a primitive called "pseudo carry". It avoids the computation of p_i and g_i, but on the other hand the carry has to be deduced from the "pseudo carry". The trick is that this late computation is overlapped by the "BK" cells delays. Consequently this adder is faster (a little bit) than the corresponding "BK" adder. The VHDL synthesis from the applet takes advantage of that.
 - "CS" Cell In the "CS" cell, the weighted sum of the outputs equals the weighted sum of the inputs. In other words "a + b + c + d + e = 2*h + 2*g + f". The "CS" cell is not only a "5 \Rightarrow 3 counter", but moreover the output "h" is never dependent on the input "e".

Carry The "CS" cell does not propagate the input carry "e" to the output "h". It makes "carry propagation free" adders possible. The number of necessary "CS" cells is precisely

free adder given by the number of digits to be added.

On the other hand each digit is coded onto 2 bits and the digit value is the sum of those 2 bits. Therefore the possible digit values are '0', '1' and '2'.

This notation system for integer numbers allows addition with a delay both short and <u>independent</u> of the digits number. Yet this system demands about twice as many bits as the standard binary notation for a comparable range. Consequently the same value may have several representations. The vertical arrow **1** next to the numbers value changes the representation without changing the value. Among the representations, the one with only '0' or '1' is always unique.

Multipliers

Multiplier The multiplication comes second for frequency of use.

AND gate An "AND" gate multiplies two bits. To multiply two n-bit numbers A and X. n² "AND" gates are required. The weighted sum of the n^2 gate outputs has indeed the same value as P = A * X. However this set of bit is not a number, although its value is computed as if it was a number. a∗x_

Since $\hat{A} < 2^n$ et $X < 2^n$, the product $P < 2^{2n}$ and therefore P is written with 2 n bits.

Multiplication

, a

Х

Unsigned A regular structure of "AND" gates and "FA" cells with a "consistent" assembling first produces the partial products and then reduces them to a number P. Since each "FA" cell reduces the number of bits by exactly one (while preserving the sum), the necessary number of "FA" cells is $n^2 - 2n$ (number of input bits – number of output bits). Yet in the following applet there are more "FA" than necessary since some '0' must also be reduced, to be precise just as many 0' as bits of X.

Fast Multipliers Many approaches lead to a speed improvement:

- Divide the number of partial product bits using a higher radix. •
- Use a tree structure for the "FA" cell reduction net. •
- Use "CS" cell, with a reduction power two times the one of "FA" cell. Besides • this cell allow balanced binary trees (with some difficulties).

Booth recoding Using a larger radix automatically reduces the multiplier X digits number. Let have a look on radix 4, using two times as less digit as radix 2 for the same range. The "Booth Code" ("BC" for short) is the minimally redundant symmetric radix-4 code. Digits values $\in \{-2, -1, -0, 0, 1, 2\}$. The 3-bit code picked below, known as "sign/absolute-value", has 2 notations for zero.

However the partial products are computed by a cell more complex than a simple "AND" gate.

Cell of the Check whether you are acquainted with the logic of the "B2BC" cell, which convert a **binary to "BC"** "BC" digit into "sign/absolute-value" for the generation of partial products. The sum is **converter** preserved, i.e. : $-2*x3 + x2 + x1 = (-1)^{s} * (2*M2 + M1)$:

The conversion of X requires half as many "B2BC" as bits in X.

Multiplication of
A bits by oneThe multiplication by one "BC" digit ∈ {-2, -1, -0, 0, 1, 2} adds 2 bits on top of the bits
of A: one at left to get either A or 2A, another for the input carry in case of subtraction."BC" digitSince A is signed, its sign may have to be extended to the bit added at the left.

The multiplication requires as many "CASS" cells as bits in A plus 1.

Partial products generation The multiplication first step generates from A and X a set of bits whose weighted sum is the product P. For unsigned multiplication, P most significant bit is positive, while in 2's complement it is negative.

Partial products reduction The multiplication second step reduces the partial products from the preceding step into two numbers while preserving the weighted sum. The sough after product is the sum of those two numbers. The two numbers will be added during the third step. The reduction trees synthesis follows the Dadda's algorithm, which assures the minimum counter number. If on top of that we impose to reduce as late as (or as soon as) possible then the solution is unique. The two binary number that have to be added during the third step may also be seen a one number in "CS" notation (2 bits per digit).

Example of Wallace tree The following trees reduce 8² partial products (for example the product of two 8-bit unsigned integers). The "Wallace trees" reduce "as late as possible" (key "late" on the preceding applet). The weighted sum of the 16 output bits equals the weighted sum of the 64 input bits.

Partial product
of "CS"Multiplier X and multiplicand A are now both in "CS" notation, i.e. with digits values
 $\in \{0, 1, 2\}$. We want to generate a set of bits whose weighted sum equals A * X. To
make sure that we get bits (easy to add), it is necessary that either in A or in X every
digit '2' is preceded by a '0' at its left.

- Partial products
reductionThe partial product of two "CS" is a simple bit, reduced in the very same way as for
conventional fast multiplication.
 - "xCS" cell The "xCS" cell computes the product of two digits a and x in "CS" notation. Its arithmetic equation is $2 \times b + 2 \times y + i = a \times x + z + c$ ". Furthermore the outputs "b" and "y" does not depend on "c" or "z" (no propagation).

Coding circuit The transcoder "CS2CS" passes from "CS" to "CS" while making sure that in the "CS2CS" output a '2' is always preceded by a '0'.

This permits to generate the partial product of a multiplicand A by a multiplier X both in "CS", with no overflow.

Coding circuit The transcoder "CS2BC" passes from "CS" to "BC", that is from the "carry-save" "CS2BC" code to the "Booth Code" (symmetric minimally redundant radix-4 code).

Integer constants multiplications

Multiplication of a variable by integer constants	The discrete Fourier transform, the discrete cosine transform or if filters, and so on, all contain the multiplication of a variable X by se C1, C2, Cn. The factorization of those constants permits a dramatic r number of additions/subtractions demanded by those multiplications. applet computes Y1 = X*C1, Y2 = X*C2, Yn = X*Cn.	inverse, digital veral constants reduction of the The following

	Step 6 : cost = 5 additions and 2 subtractions	

Dividers

Weighting a
bread loaf with
restoration and
without
restorationWe want to computer $Q = A \div D$. By a stroke of luck, we have available a scale, a
white bread whose weight is actually just A and a set of weights with values D, 2D,
 $4D, 8D, \dots 2^{i*}D$ respectively marked with 1, 2, 4, 8, $\dots 2^{i}$.In fact D is a binary number, and $2^{i*}D$ is simply obtained by shifting D. The scale
compares the sum of the weights on each of the two plates (\leq or >).

Digit recurrence division Division is not frequent. Nevertheless since its execution delay is far larger than the addition or multiplication's one, its contribution to the total execution time is substantial, thus it is advisable to design dividers carefully.

Let say that we want $Q = A \div D$. This is equivalent to Q * D = A. Therefore if Q and D are both written onto n bits, A is written onto 2n bits.

Let us build a series Q_n , Q_{n-1} , ..., Q_2 , Q_1 , Q_0 and a series R_n , R_{n-1} , ..., R_2 , R_1 , R_0 such that the invariant $A = Q_j * D + R_j$ holds for all j.

The recurrence is :

- $\bullet \quad Q_{j\text{-}1} = Q_j + q_{j\text{-}1} \, \ast \, 2^{j\text{-}1}$
- $R_{j-1} = R_j q_{j-1} * D * 2^{j-1}$

with initial conditions:

- $Q_n = 0$
- $R_n = A$.

When the recurrence stops, we have $Q = Q_0 = \sum_{i=0}^{n} q_i * 2^i$. $R = R_0$ is the division remainder.

Conditional A "conditional subtractor" gives the following result S:

subtractor if R < D then S = R else S = R - D;

Each "SC" cell computes both the result and the carry (borrow) of the subtraction R - D. If the output carry value (leftmost) is '1' then S is assigned the result of the subtraction else S is assigned the value of R. This last case, that seems to "restore" R to its previous value before the subtraction is sometimes called "restoration", from which the divider's name derives,

The "conditional subtractor" function: if R < D then S = R else S = R - D, is abstracted by its transfer function called "Robertson's diagram". To converge the division imposes moreover that $0 \le R \le 2*D$.

Restoring A "restoring" divider consists in a series of shifts and attempted subtraction. It is made of a regular net of conditional subtraction cell "SC" (subtraction or nothing according to a carry out bit).

Fast dividers Three approaches may be combined to realize fast dividers:

- Utilization of <u>carry-propagation-free</u> addition/subtraction.
- Preconditioning of the dividend and the divisor in order to simplify the division.
- Use of higher radixes to reduce the number of steps.

Robertson's To obtain a square Robertson's diagram, the successive partial remainders are **Diagram** normalized: $(R_j * b^{-j})$ where b is the numeration radix.

The black slopes represent the transfer function $R_j \Rightarrow R_{j-1}$, the red line is the identity function, that passes to the following step. Pulling the mouse out of the pictures suspends the animation. Clicking ends or restarts the animation. Clicking inside the square sets another starting point.

Radix 10 sounds familiar to us; it is given here just for illustration because it would not be very efficient in binary.

"SRT" division To avoid the delay of the carry propagation, the following applet uses a stack of or carry borrow-save "BS" adders/subtractors. The "tail" cell, variant of the "SC" cell, is controlled by two bits and executes one of the three following operations: propagation free

division

- •
- an addition : $R_{j-1} = R_j + 2^{j-1} * D$ a subtraction: $R_{j-1} = R_j 2^{j-1} * D$ •
- an identity: $R_{i-1} = R_i$ •

This operation is selected according to the sign of the partial remainders R_i. To always know precisely this sign would require the examination of all the remainder's digits. It is sufficient to check only three. Moreover, the position of the three digits is known: the rightmost one is aligned with the most significant non-zero bits of D. To nail down this digit position, D is "normalized", that is the position of its first "1" bit is fixed. For an n-bit divider, $2^{n-2} - 1 < D < 2^{n-1}$.

Conditional A "conditional adder/subtractor" yields one among the three following outputs:

carrypropagation-free adder/subtractor

- **if** q = -1 **then** S = R + D ;
- **if** q = 0' **then** S = R; •
- **if** q = '1' **then** S = R D;

Each "tail" cell executes a one-bit addition/subtraction. The carry is not propagated to the "tail" cell at left but fed directly to the "tail" cell below (next line).

The "conditional adder/subtractor" function sis abstracted by its transfer function called "Robertson's diagram". To converge the division imposes moreover that

 $-2*D \le R \le 2*D$. If $-D \le R \le 2$ then S has two possible values.

"tail" cell of the Check whether you are acquainted with the logic of the "tail" cell.

"SRT" divider

•

- **if** q = 0' **then** $2*s_1 s_0 = r_0$; // identity
- **if** $q = \frac{1}{then} 2 s_1 s_0 = \overline{d_0} + r_0$; // subtraction

if q = -1' **then** $2 * s_1 - s_0 = d_0 + r_0$; // addition

''head'' cell of the ''SRT'' divider Let $\hat{R} = r_{2}*4 + r_{1}*2 + r_{0}$ and $\hat{S} = s_{2}*4 + s_{1}*2 + s_{0}$ be the input and output values of the "head" cell. Another output is one quotient digit q.

- **if** $\hat{R} > 0$ **then** { $\hat{S} = \hat{R} 2$; q = '1'; }
- **if** $\hat{R} = 0$ **then** { $\hat{S} = \hat{R}$; q = 0' ; }
- **if** $\hat{R} < 0$ **then** { $\hat{S} = \hat{R} + 1$; q = '-1'; }

In a real division (without overflow), output s_2 will <u>always</u> be 0. .

"SRT" division with divider range reduction **The previous division is simple because the fist bit of the divider D is always "1". It may be even further simplified if the <u>two first bits</u> d_0 and d_1 of the divider D are reduced to "1 0" thanks to the following operation: if** d_1 there (D - D + 2/4 + A)

if d_1 then $\{ \ D=D*3/4 \ ; \ A=A*3/4 \ ; \ \}$.

This multiplication of A and D by the same constant does not alter the quotient Q, but on the other hand the final remainder R is also multiplied.

For an n-bit divider, $2^{n-1} - 1 < D < 2^{n-1} + 2^{n-2}$.

Head cell of the "SRT" divider with range raduction Let $\hat{R} = r_1 * 2 + r_0$ be the "head" cell input value. • if $\hat{R} > 1$ then { $s_0 = \hat{R} - 3$; q = +1; }

Arithmetic operators Page 25

reduction

- **if** $\hat{R}=1$ **then** { $s_0=0$; q=-0 ; }
- if $\hat{R}=0$ then { $s_0=0$; q=+0 ; } or { $s_0=-1$; q=-0 ; }
- if $\hat{R} = -1$ then { $s_0 = -1$; q = +0 ; }
- **if** $\hat{R} < -1$ **then** { $s_0 = \hat{R} + 2$; q = -1 ; }

Here the difference between the two 0 representations for q : "- 0" and "+ 0" matters.

Quotient The quotient Q is in redundant notation. The conversion into a conventional binary representation is obtained thank to an adder (in fact a subtractor). Since the digits q are obtained sequentially, most significant digit first, the conversion can be carried out in parallel with the quotient digits obtaining. Let "ratio" be the "head" cell and "BK" cell delays ratio. The higher the ratio, the simpler the converter.

Divider design The quotient Q digits are redundant and symmetrical. Therefore they are completely defined by the radix and the maximum digit value. This applet let you choose the quotient digit values and then the necessary number of bits from divider D and digit from partial remainder R that must be taken into account for the selection of the quotient digit value.

Arithmetic operators Page 27

The leftmost button moves to the next or to the previous step.

- 1- Robertson's diagram, plotting the next partial remainder according to the current partial remainder. The boundaries take divisor D into account.
- 2- Symmetrical PD-plot for D in the range [1/2 , 1 [
- **3-** Half PD-plot, upper part of the preceding one. The lower part is obtained by changing the sign.
- 4- Discretised half PD-plot. The number of D bits taken into account gives the abscissa discretisation, while the number of P digits gives the ordinate discretization. Fixing this number of bits/digits will determine whether a continuous frontier can separate the different values of q.
- **5-** Half truth table for the half PD-plot.

Square root extractor

Square root extraction The square-root extraction is relatively rare. Nevertheless, it is used among other things for Euclidean distance and least square and is included in the floating-point standard. The square-root operator is similar to the one for division, therefore most of what we already know about division may apply as well to square root. Often the same operator is used either for division or for extraction, collision of the two operations being too rare to justify two operators, moreover each very costly.

Square root In the drawing below, the area of each red rectangle represents one bit weight. Only **extraction** the '1' are drawn. Therefore the total area is the weighted sum of all the bits.

algorithm The goal of the game is to find a square with an area equal to a given argument, represented by the area of a blue circle, just by observing one test bit (\leq or >) and by clicking the square side bits. After convergence the sough after number is the side of the square.

Square root We want to get $Q = \sqrt{A}$. This is equivalent to $Q = A \div Q$. Therefore if Q is written **extractor** on n bits, A is written on 2n bits.

Let us build a series Q_n , Q_{n-1} , ..., Q_2 , Q_1 , Q_0 and a series R_{2n} , R_{2n-2} , ..., R_4 , R_2 , R_0 such that the invariant $A = Q_j * Q_j + R_{2j}$ holds for all j.

The recurrence is:

- $Q_{j-1} = Q_j + q_{j-1} * 2^{j-1}$
- $R_{2j-2} = R_{2j} q_{j-1} * 2^{j-1} * (2 * Q_j + 2^{j-1})$

with the initial conditions:

- $Q_n = 0$
- $R_{2n} = A$.

When the recurrence ends, we have $Q = Q_0 = \sum_{i=0}^{n} q_i * 2^i$. R = R₀ is the final remainder of the square root extraction.

Realization The restoring square-root extractor utilizes the same conditional subtractor "SC" cells as the non-restoring divider.

Fast square-root We want to get rid of the carry propagation by the use of the "BS" notation, the same

- **extractor** "head" and "tail" cell and architecture similar to the fast division. We bump into three difficulties when trying to use the fast divider for extraction of square roots.
- **Square root converter** The first difficulty is the root feedback. In a similar way as the division, the extractor supplies a partial root Q_j in "BS" notation. On the other hand, the "head" and "tail" cell of the divider accepts a partial root in conventional binary representation. A subtractor could be used to convert each Q_j from "BS" to conventional, but that would be both slow and expansive. The converter below use a 4-input, 2-output "trc" cell, derived from the "BK" cell.

Square root Check whether you are acquainted with the logic of "trc" cell, which convert from **conversion cell** "BS" notation into standard binary notation.

Input "si" is a bit from Q_j , input "ci" indicates whether the carry propagates in this cell's position. The carry is used in case of subtraction of 1. This signal corresponds to the value 'P' of the "BK" cell.

- if $q_j = -1$ then { so = si \oplus ci ; co = 0 }//subtraction (sum carry), carry killed
- **if** $q_i = 0$ **then** { so = si ; co = ci } //sum unchanged, carry propagated
- if $q_i = 1$ then { so = si ; co = 0 } //sum unchanged, carry killed

Carry- The fast square-root extractor utilizes the same cell as the fast divider to execute at each step one of the three following arithmetic operations:

square root

- **if** $q_i = -1'$ **then** $R_{2i-2} = R_{2i} + 2^j * Q_i 2^{2j-1'} //$ addition
- **if** $q_j = 0'$ **then** $R_{2j-2} = R_{2j} //$ identity
- **if** $q_j = '1'$ **then** $R_{2j-2} = R_{2j} 2^j * Q_j 2^{2j-1}$ //subtraction

Each "head" cell selects the value of one q_j thanks to the sign of an approximate \hat{R}_{2j} of the current remainder R_{2j} .

The second difficulty with respect to division lies in the subtraction of 2^{2j-1} whenever $q_j = -1$ or $q_j = 1$. For the bit subtraction, a negative input of the least significant tail cell of each line is used.

The third difficulty lies in the range of Q. Indeed each Q_j must start with a "1" in the most significant position (implicit). This condition is fulfilled if the two most significant bits of the radicand A are not both zero. This "1" is subtracted from A in the first line thanks to a negative "head" input

Floating-point addition

Floating-point numbers format numbers format i The binary code of floating point real numbers is composed of three fields. The sign S (1 bit), the exponent E (8 bits) and the mantissa M, or significand (23 bits). The number value is $(-1)^{S} * 2^{(E - 127)} * (1 + M / 8388608)$. However if E = 0, the number value is $(-1)^{S} * 2^{(-126)} * (M / 8388608)$ and if E = 255, the value is infinite. Check your understanding of this format by entering the code (32 bits) of the proposed numbers.

Addition and Since real numbers are coded as "sign/absolute-value", toggling the sign-bit inverses the sign. Consequently the same operator performs as well either addition or subtraction according to the operand's sign.

Addition/subtraction of two real numbers S = A + B is more complex than multiplication or division or real numbers.

Floating-point addition progresses in 4 steps:

- Mantissa alignment if A and B exponents are different,
- Addition/subtraction of the aligned mantissas,
- Postnormalization of the mantissas sum S if not already normalized,
- Rounding of sum S.

The alignment step yields a guard bit and a sticky bit for the rounding step.

A 55	B 5.5

Adder/ A floating-point adder is made of the following blocks:

subtractor Bloc 1: outputs the larger of the two exponents (8 bits), outputs the exponent distance (5 bits), outputs the implicit bit of both operands.

Bloc 2: outputs at left the smaller operand mantissa (23 bits), outputs at right the larger operand mantissa (23 bits).

Shifter 1: shifts to the right the smaller operand mantissa, adds the guard bit and the sticky bit, totaling 26 bits.

Complementer: on request, does the logic complement for a subtraction.

Adder 1: adds the two inputs and the carry in. outputs the rounded sum and a carry out.

Zero-leading-counter: the ZLC output gives the number of leading '0' if the result is not normalized, and "1" otherwise.

Shifter 2: shifts to the left (ZLC - 1) positions. The fist bit is lost (implicit '1'). Adder 2: subtracts (ZLC - 1) from the greater of the two exponents.

Real numbers fast addition fast addition additi

Zero leading A binary tree counts up the number of '0' in the most significant positions by dichotomy. If the size of the sub-strings is a power of two, then there is no need for adders but multiplexors can be used instead. Indeed only the size of the left subsrting has to be a power of two. The substring at right must simply be shorter than or of the same size as the left subsrting.

Zero leading This cell combines the number of leading '0' of two 16-bit strings to obtain the number of leading '0' of the concatenation of the two strings.

• if X < 16 then S = X else S = 16 + Y

Zero leading prediction From the mantissas A and B, one can construct in constant time a string P with the same number of leading zeroes, but for at most one, as the <u>result</u> of the difference D = A - B with no need to wait for the subtraction completion. When fed to a ZLC, this string predicts the number of positions required by the shifter. If the result of the shift still exhibits a leading zero, then a shift of one more position is necessary to normalize the result. Otherwise the shifted value is normalized.

The prediction is valid if A is normalized and B less than or equal to A. This is the always the case in a significand subtraction. The leading zero(es) result from a carry string 'P'* 'G' 'K'*, made up with a number (possibly null) of 'P' followed by an unique 'G' followed by a number (possibly null) of 'K'. The predictor cell outputs a '0' for every pair of symbols in: 'P' 'P'; 'P' 'G'; 'G' 'K' et 'K' 'K' and outputs a '1' for every other pair.

This predictor does not take into account the carry propagation that may lead to an error of one position in the predicted bitstring. Since only one bit in 'P'* 'G' 'K'* might be incorrectly predicted, the error is tolerable.

Zero leading The prediction is incorrect only if the carry string <u>starts</u> with 'P'* 'G' 'K'* 'P'* 'K'. The following circuit output 'Y' whenever the prediction is incorrect, in other words too small by one.

Z indicates a string 'K'* 'P'*

Q indicates a string 'P'* 'G' 'K'* 'P'* (containing only one 'G') N indicates a string <u>starting with</u> 'P'* 'K' Y indicates a string <u>starting with</u> 'P'* 'G' 'K'* 'P'* 'K', that is Q followed by N. U indicates any other string.

Prediction cell The leading '0' prediction cell output a '1' at the end of the string 'P'* 'G' 'K'* and '0' inside the string (and don't care neither inside nor at the end). Check whether you are acquainted with the truth table of this cell.

Elementary Functions

Elementary Realization of operators for Exponential, Logarithm, Sine, Cosine, arcTangent functions relying on addition/subtraction and fixed shift. The cost and delay of fixed shits are negligible when they are wired.

the exponential computation

From a bread We want to compute exp (Y), we have available a scale, a white bread whose loaf weighting to weight is actually just Y and a set of weights with values $log(1 + 2^{-i})$. The weighting gives the sought-after result in the form of a product of rationals $(2^{i} + 1) / 2^{i}$. The multiplication by each rational amount to a mere addition and shift.

> A weight put down on the right plate (the bread's one) has it value changed into $-\log(1-2^{-1})$. Thank to this trick, the weighting can be restoring, non-restoring or "SRT".

Carry The scale is replaced by a "SRT" divider whose "Robertson's diagram" is drawn propagation free below

division for exponential

"SRT" divider The constants $log(1 + 2^{-i})$ and $-log(1 - 2^{-i})$ fed into the "tail" cells are wired. Thus for exponential there are 4 variants for the cell according to the values of the two bits.

Operations of a slice of "SRT" The value of each q_j is selected by a "head" cell according to \hat{R}_j , the weighted sum of the two most significant digits r_1 and r_0 of the representation of R_j .

divider for exponential

• if $\hat{R}_{j} > 0$ then { $q_{j} = '1'$; $s_{0} = \hat{R}_{j} - 2$; $R_{j+1} = R_{j} + \log(1 - 2^{-j})$ } // subtraction • if $\hat{R}_{j} = 0$ or $\hat{R}_{j} = -1$ then { $q_{j} = '0'$; $s_{0} = \hat{R}_{j}$; $R_{j+1} = R_{j} + 0$ } // identity • if $\hat{R}_{j} < -1$ then { $q_{j} = '-1'$; $s_{0} = \hat{R}_{j} + 2$; $R_{j+1} = R_{j} + \log(1 + 2^{-j})$ } //addition

Suite de The stack of conditional multipliers by 1 or by $(1 + 2^{-i})$ or by $(1 - 2^{-i})$ needs only **multiplications** one final carry propagation thanks to <u>"CS" adders</u> and wired shifts.

Additions are truncated to 2 n digits, of which two before the point. The third most significant digit (fully left) is the sign. Despite the fact that all partial results are positive, the execution of subtraction in "CS" sometimes brings about an unresolved sign. The final result (bottom line) must be converted from "CS" to binary by one

addition (with carry propagation).

La fenêtre du bas permet de comparer le produit "vraie" des multiplications (sans troncature) au produit avec troncature.

Numerical example of divisionThe tables below shows the partial remainders ("BS") and the partial products ("CS"). The windows at the tables bottom gives the actual value of the function, the product of rationals $(1 + 2^{-i})$ or $(1 - 2^{-i})$.and finally the truncated product of rationals to exhibit the errors introduced by the method

The series of rational products is given by the concatenation of the quotient Q (left) and the final remainder R (bottom). Actually for high values of i, $2^i * \log(1+2^{-i})$ becomes very close to 1. If the divider is close 1, then the remainder becomes an acceptable approximation for the quotient.

Range extension The previous circuit works with Y in the range] -1, +1 [. For the exponential of any number Y, Y is written Y = Q*log(8) + R, where Q is the integer quotient of the division of Y by log(8) and R < log(8) < 1. Then $exp(Y) = 8^{Q} * exp(R) = 2^{3Q} * exp(R)$. Since exp(R) < 1, it is acceptable by the above circuit.

Logarithm and exponential

The same operator computes either the Logarithm or the Exponential with additions/subtractions (it is the same operation), shifts and constants. The constants are $log(1 + 2^{-i})$ and $-log(1 - 2^{-i})$ and the digits $\in \{ -1, 0, 0, -1, 0 \}$. The slack selection of the digit value, which unfortunately will be lacking later on for Sine and Cosine, allows to avoid all but one carry propagation

From a bread We want to compute sine(A) and/or cosine (A); we have available a scale, a white bread whose weight is actually just A and a set of weights with values arctg (2⁻ⁱ). All the weights must go on the scale plates, either side.

Sine and Cosine Let V_i be a vector, with extremity (x_i, y_i) . A "pseudoRotation" of an angle arctg (2^{-i}) **computation** applied to V_i gives $V_{i+1} : x_{i+1} = x_i - y_i * 2^{-i}$ and $y_{i+1} = y_i + x_i * 2^{-i}$. After the angle A is broken down into a weighted sum of arctg (2^{-i}) , a series of "pseudoRotations" yields the coordinates of the vector of angle A, those coordinate are the values sin(A) and cos(A) searched for. All the "pseudoRotations" require only addition/subtraction and shift.

The constant k Each "pseudoRotation" of the angle $arctg(2^{i})$ brings about a vector lengthening of $\sqrt{1+2^{-2i}}$, for it is not exactly a rotation but rather a displacement of the vector extremity on a perpendicular vector. In order to compensate in advance the product of all the lengthening of a series of "pseudoRotations", the starting vector is ($x_0 = k$, $y_0 = 0$). For n large enough, \mathbf{k} is approximately equal to 0,60725. In order for \mathbf{k} to be a constant, the representation with $arctg(2^{-i})$ use digits $\in \{ -1^{\prime}, -1^{\prime} \}$

Angle What is the domain of the angles $A = \sum_{i=0}^{n} a_i * \arctan(2^{-i})$ and what precision can be decomposition expected from this notation ? A is the angle value to reach, and T is the value attained by the series of pseudoRotations. To change the value of A, click in the figure. All values are expressed in radiant. The key "Mise à zéro" allow to 'manually' control the convergence into the notation $\operatorname{arctg}(2^{-1})$ by clicking the digit values.

"Robertson's The "Robertson's diagram" shows that the iteration to convert into basis $\arctan(2^{-i})$ diagram" for may be as follows:

CORDIC if $R \ge 0$ then $\{S = R - \arctan(2^{-i}); a_i = '1'\}$ else $\{S = R + \arctan(2^{-i}); a_i = '-1'\}$.

"non restoring" The angle Y (divider's top) is in the interval [-1.743... +1.743...]. The constant bits at **"AS" cells** inputs are wired. The operations are selected according to the previous partial remainder R or by y₀ for the first iteration ..

''double rotation'' CORDIC '' Robertson's It uses an approximation \hat{R} of the partial remainder R to determine the rotation: **i**t $\hat{R} > 0$ **then** { $a_i = '1'$ }; **i**f $\hat{R} = 0$ **then** { $a_i = '0'$ }; **i**f $\hat{R} < 0$ **then** { $a_i = '-1'$ } The diagram shows that the approximation can be coarse.

Diagramme''

"double This divider uses the same <u>"head"</u> and <u>"tail"</u> cells as the "SRT" divider. To put up **rotation"** with the '0', the angle is first halved then the "pseudoRotation" are doubled. Thanks **CORDIC** to that, the lengthening stays the same $(2*\sqrt{1+4^{-1}})$ whatever the value of a_i .

- **if** $a_i = -1$ then { rotation of $(\arctan(2^{-i}))$ then rotation of $(\arctan(2^{-i}))$ };
- **if** $a_i = 0^{\circ}$ **then** { rotation of $(\arctan(2^{-i}))$ then rotation of $(-\arctan(2^{-i}))$ };
- **if** $a_i = '1'$ **then** { rotation of $(-\arctan(2^{-i}))$ then rotation of $(-\arctan(2^{-i}))$ };

"head" of divider1

"head" of divider2

if $\hat{R} > 0$ then { $\hat{S} = \hat{R} - 2$; $a_i = '1'$; } if $\hat{R} \le 0$ then { $\hat{S} = \hat{R} - 2$; $a_i = '1'$; } if $\hat{R} \le 0$ then { $\hat{S} = \hat{R} - 2$; $a_i = '1'$; } It is clear that whenever $\hat{R} = 0$, divider1 speculates that R < 0 and divider2 that R > 0. At most one of them will eventually overflow, before the occurrence of the next $\hat{R} = 0$. An overflow indicates that the correct output is the other divider's one. Only divider1 is shown by the following applet.

The two heads detect the overflow to produce together a 3-valued indicator :

'K' the output digit is correct (either divider1 and divider2 give the same value, or divider2 overflows), 'G' the output digit is incorrect and must be complemented (divider1 overflows), 'P' propagate the next indicator's value (values differ, no overflow). Whenever a divider overflows, it carries on with the other divider's partial remainder R.

The propagation is similar to the <u>carry propagation</u> of addition..

Numerical The "Nb. bits" selects simultaneously the number of bits of the calculations and the number of steps. Clicking the vertical arrow **1** changes the representation. Again, the key "Mise à zéro" allows to control 'manually' the convergence.

Arithmetic operators Page 49

Modular Arithmetic

Modular Let be the set { $m_1, m_2, m_3, ..., m_n$ } of n integer constant pairwise prime called moduli and let M be the product of this constants, $M = m_1 * m_2 * m_3 * ... * m_n$.

Let A be an integer smaller than M.

A can be written $(a_1 | a_2 | a_3 | \dots | a_n)_{RNS}$ where $a_i = A$ modulo m_i (residue).

This definition tells how to get the a_i from A. On the other hand it is possible to get back A from the a_i using another set of precomputed constants { $im_1, im_2, im_3, ... im_n$ } called inverse modulo M of the former.

 $A = | a_1 * im_1 + a_2 * im_2 + a_3 * im_3 + \dots a_n * im_n |_{modulo M}$

This result is proved in the "Chinese remainder theorem". Check if you are acquainted with this representation by converting A from "decimal to RNS" or from "RNS to decimal".

Modular Modular addition uses n <u>small</u> adders computing <u>simultaneously</u> all the sums addition $s_i = |a_i + b_i|_{modulo} m_i$.

Modular Modular subtraction uses n <u>small</u> subtractors computing <u>simultaneously</u> all the **Subtraction** differences $d_i = |a_i + m_i - b_i|_{modulo} m_i$.

Conversion into
RNSThe conversion of a binary variable A into RNS consists in finding all $a_i = A$ modulo
 m_i i.e. the remainders of the division of A by m_i . But the division is not the best
approach.

- the rest modulo 2^n is immediate,
- the rest modulo $2^n 1$ requires only additions,
- the rest modulo $2^n + 1$ requires some additions and some subtractions.

In other cases we resort to the one of the two last expressions with the smallest n. Trees of adders (Wallace trees) reduce A to the sum of two n-bit numbers while respecting the rest modulo m_i .

The graphical conventions are the same as for partial products reduction .

Example of modulo The following applet reduces 64 bits into 6 bits whereas preserving the value modulo 63 ($63 = 2^6 - 1$). At the output, zero has two notations: either "000 000" or "111 111"

modulo $2^{n}-1$ The "end-around-carry" adder offers two advantages : it works fine modulo $2^{n} - 1$ **adder** and is simple, and two disadvantages as well : it is slow and difficult to test, both for the same raison i.e. for the value zero are two stable cases.

An adder delivers spontaneously a modulo 2^n sum. With a slight modification, the <u>Sklanski</u>'s adder delivers a modulo $2^n - 1$ sum S.

- **if** $A + B < 2^n 1$ **then** S = A + B;
- **if** $A + B \ge 2^n 1$ **then** $S = |A + B + 1|_{modulo 2} n$

The condition is given by the carry out c_n : if $c_n = 'K'$ then $A + B < 2^n - 1$, if $c_n = 'P'$ then $A + B = 2^n - 1$, if $c_n = 'G'$ then $A + B > 2^n - 1$. The "feed-back" signal that controls the "+1" is 'K' if $c_n = 'K'$ and 'G' otherwise.

modulo $2^{n} + 1$ We now want an adder modulo $2^{n} + 1$.

adder •

if A + B < 2ⁿ + 1 then S = A + B;
if A + B ≥ 2ⁿ + 1 then S = | A + B - 1 | modulo 2 n

The previous adder is used with two numbers X and Y such that $X + Y = A + B + 2^n - 1$. A row of HA' cells carries on this addition propagation-free. HA' is the dual of HA.

- **if** $X + Y < 2^{n+1}$ **then** $S = |X + Y + 1|_{modulo 2^n}$;
- **if** $X + Y \ge 2^{n+1}$ **then** $S = |X + Y|_{modulo 2^n}$;

The "feed-back" signal that controls the "+1" is the "nand" of x_n and $(c_n = 'K')$. The result bit s_n is the "and" of x_n and $(c_n = 'P')$.

Conversion
from ''RNS''The "Mixed Radix System" is a positional number system with weights (1) (m_1)
(m_1m_2) ($m_1m_2m_3$) ($m_1m_2m_3$, m_{n-1}).into mixed-radix
system ''MRS''In this system X is written ($z_1 | z_2 | z_3 | | z_n$)_{MRS} with $0 \le z_i < m_i$. Note that the digit
set have the same range as the RNS digits, but the digits themselves are different.The value of $X = z_1 + m_2 + (z_2 + m_3) + (z_2 + m_3) + (z_3 + m_3) + (z_4 + m_4) + (z_4 + m_3) + (z_4 + m_4) + (z_4 + m_4)$
